Dr. Krishan Khurana
Prof. Margaret Kivelson
Saturn's Magnetosphere

Saturn exhibits a nearly dipolar field, the magnetic equator being slightly shifted northwards due to quadrupolar term. Different characteristics are encountered at different distances from the planet.
Enceladus

- $R \sim 3.95 \, R_S$
- Ice crust, liquid interior ocean
- 2:1 Tidal locking with Dione

GEOLOGICAL ACTIVITY

- Cryovolcanoes in southern pole region
- Mass loading rate $\sim 200 \, \text{kg/s}$
- $\text{H}_2\text{O}$, traces of molecular nitrogen, methane, and carbon dioxide
- Enceladus’ geysers are the main source of Saturn’s plasma sheet

Image credit: JPL/NASA
Cassini MAG Data
Ion cyclotron waves are transverse plasma waves typical of regions where the total pressure is dominated by the magnetic pressure and the velocity distribution of ions is non-Maxwellian.

- Quasi circular polarization in perpendicular components
- Propagation mostly along magnetic field lines ($\mathbf{k} \times \mathbf{B} = 0$)
- Dominant in regions up to $\sim 6 R_S$
- $B_R, B_\phi$ components!

Resonant ions produced mostly by charge exchange due to interaction between neutral species ejected plumes and corotating plasma.

- Local time dependence
- R dependence
- Amplitudes up to 2.3 nT
- Frequencies close to gyrofrequencies of water group ions

Ion Cyclotron Waves (3)

Power spectral density generated using Splash and plotted on MATLAB.

- Δt ∼ 8.3 minute
- 4.58 Rs
- 12/24/2005
- running avg ∼ 8

SPLASH/MATLAB generated PSD plot in the three components
For instance, let us look at a 5 min signal in one of the perpendicular magnetic field components, $B_\phi$. 

---

Ion Cyclotron Waves (4)
$H_3O^+$ gyrofrequency

$f \sim 0.147$ Hz
What determines ICWs amplitude?

Pick-up ion densities drive the fluctuation amplitude.

- Densities of neutral species
- Plasma sheet ion densities
- Pick-up velocity (keplerian, corotational)

MATLAB plot for Amplitude vs. total neutral density

- Local Time
- Radial distance
- Distance from magnetic equator
Mirror Modes

Mirror modes are plasma instabilities typical of regions with strong temperature anisotropies. Differently from ICWs, they USUALLY prosper in high $\beta$ environments, such as planetary magnetosheaths.

- Highly irregular occurrence
- ~ Non-propagating along field lines
- Parallel field component $B_\theta$
- Frequencies lower than ICWs frequencies
- Local Time dependence
- Dominate total B fluctuations at $R > 6R_S$

MMs: Instability Condition

Instability initially treated as MHD fluid instability. For a complete treatment based on kinetic theory see Hasegawa 1969.

\[ 1 + \beta_k \left( 1 - \frac{T_i}{T_{ii}} \right) < 0 \]

Instability condition

\[ -\frac{\gamma}{k_{ii}} = \frac{B^2}{\mu_0} \frac{1 + \beta_k \left( 1 - \frac{T_i}{T_{ii}} \right)}{2 \pi (T_{ii}^2 / T_{ii}) F_{res}} \]

Growth rate (Kivelson and Southwood, 1993)

Inverse proportionality with distribution function of resonant particles!
As suggested by Southwood and Kivelson (1993), particles can be separated into two classes when analyzing the physical mechanism leading to MMs.

**BULK PLASMA PARTICLES** (high parallel velocity): these particles move along field lines and encounter a *spatial field variation*. They exchange kinetic energy between the parallel and perpendicular components.

**RESONANT PARTICLES** (low parallel velocity) do not move a significant distance along the field in the instability growth time $1/\gamma$. *Their kinetic energy is not conserved.*
ICWs

vs.

MMs
ICWs
4.58 \( R_s \); 24/12/05

VS.

MMs
6.83 \( R_s \); 24/12/05
The instability condition depends on the strength of magnetic field and on the plasma temperature anisotropy:

$$1 + \beta_\perp \left( 1 - \frac{T_\perp}{T_\parallel} \right) < 0$$

If the perpendicular plasma $\beta$-parameter is known, it can be used to calibrate a lower limit for the temperature anisotropy coefficient:

$$c_\alpha = \frac{T_\perp}{T_\parallel}$$

Sergis et al., Particle pressure, inertial force, and ring current density profiles in the magnetosphere of Saturn, based on Cassini measurements, 2010
We observed mirror mode instabilities up to 5.84 $R_S$ for a daytime low inclination orbit in the Feb2005 dataset.

A value for the anisotropy coefficient $c_a \sim 10.5 \div 11.0$ is obtained using the fit for total particle pressure by Sergis et al. 2010. Such value is not consistent with that obtained by Wilson et al. 2008 for water group ions ($c_a \sim 3 \div 8$) in the region near 5.5 $R_S$.

$$p = \frac{2p_\perp + p_\parallel}{3}$$
MMs: Instability Condition (4)

\[ c_a \sim 8.5 \div 9.0 \]

\[ 5.84 \text{ } R_s \]
We can think of inserting a correction parameter $b$, taking into account various effects which lead to uncertainty on the value of $\beta_\perp$ (such as unavailable electron moments at $R \sim 10 \ R_s$, large scatter of fit). For $b = 1.5$:

$$c_\alpha \sim 6.0 \div 6.5$$

in agreement with CAPS measurements.
Summary of Results

• PSD constructed starting MAG data: presence of ICWs at frequencies close to water group ions gyrofrequencies
• ICWs are the main contribution to magnetic field fluctuations up to 6Rₛ.
• ICWs max amplitudes ~ 2.3 nT near the magnetic equator.
• Short lived ion cyclotron episodes in dayside orbits.
• No simple polynomial or logarithmic relation between ICWs amplitudes and neutral species densities.
• Mirror mode instability dominates at r > 6Rₛ, we suggest this is due to lower density of ion cyclotron resonant particles.
• Evident mirror mode structure distribution is quite irregular with respect to ICWs: large silent regions with almost no field fluctuations.
• Temperature anisotropy lower limit derived by fitting Cassini Magnetometer and Cassini Plasma Spectrometer data of \( c_a \sim 8.5 \div 9.0 \).
• **Solar Probe +** will orbit close to the Sun, among scientific goals investigation of coronal heating problem: wave heating or magnetic reconnection?

• **Juno** mission to Jupiter: study of magnetic phenomena in polar regions
